24 INTRODUCTION

25

26 The strongest San Francisco Bay area earthquake since the 1989 $M=7.0$ Loma Prieta
27 shock struck south of Napa, California, on August 24, 2014. Field mapping revealed
28 (Dawson *et al.*, 2014; EERI, 2014; Brocher *et al.*, 2015) and seismic and geodetic source
29 inversions (Barnhart *et al.*, 2015; Dreger *et al.*, 2015; Wei *et al.*, 2015) confirm that a 15-km-
30 long NW-trending section of the West Napa Valley fault ruptured in the earthquake, the first
31 indisputable surface-rupturing earthquake in the Bay area since 1906. This event, along with
32 other smaller earthquakes on the Calaveras and Hayward faults over the past 3-4 decades,
33 may indicate that the Bay area region is emerging from the stress shadow of the 1906 $M=7.8$
34 San Francisco earthquake (Harris and Simpson, 1998; Pollitz *et al.*, 2004). In the broader Bay
35 area, there have been 113 $M \geq 4.1$ shocks during the 36-yr period since 1979, nine with $M \geq 5.5$
36 ($M=4.1$ is the magnitude of completeness). In the preceding 36 yr, there were 81 $M \geq 4.1$
37 shocks, only two with $M \geq 5.5$. Most of the events $M \geq 4.1$ since about 1979 are concentrated in
38 a corridor extending north from the 1989 Loma Prieta aftershock zone through the Calaveras,
39 Greenville, Green Valley, Napa, and Rogers Creek faults east of the Bay (Fig. 1a). This
40 corridor roughly coincides with the 1906 stress shadow that is being eroded away by more
41 than a century of stress re-accumulation. The Napa event, as well as the surrounding faults on
42 which we calculate the resulting hazard increases, all lie within this reawakening zone.

43 Despite a very low aftershock productivity, the South Napa $M=6$ earthquake has a
44 high proportion of remote aftershocks. We therefore explore how stress imparted by the 2014
45 mainshock changed the surrounding seismicity, and we estimate the influence of the South
46 Napa shock on stress and future seismic hazard on the densely populated Bay Area faults
47 nearby. We find that, in addition to the sections of the West Napa fault to the north and south
48 of the rupture, the Concord-Green Valley fault experienced a transient seismicity rate
49 increase, and we calculate it sustained a Coulomb stress increase that raises the likelihood of
50 $M \geq 7$ Green Valley ruptures by about 3% for the next several decades. A 5-km-long echelon
51 at the junction of the Rodgers Creek and Hayward faults also received a calculated 0.5-bar
52 stress increase and a seismicity rate jump.

53

54 AFTERSHOCK PRODUCTIVITY AND SEISMICITY RATE CHANGE

55

56 The South Napa aftershock productivity is very low relative to other M~6.0
57 California earthquakes (Brocher *et al.*, 2015), which we probe in Fig. 2 and Table 2. But
58 although the aftershock rate is a full order of magnitude lower than the 1992 M=6.1 Joshua
59 Tree event, the South Napa mainshock triggered far more off-fault aftershocks than did the
60 2004 M=6.0 Parkfield earthquake (Bakun *et al.*, 2005). These remote aftershocks provide a
61 further basis for testing the Coulomb calculations.

62 We use the ANSS (Advanced National Seismic System) composite catalog and
63 compare the first two months of post-mainshock seismicity with the preceding 5 years in Fig.
64 3b and Fig. 3c, assuming that the detection level was constant during this period (Fig. S1).
65 Because of the low background rate and the short post-mainshock time period, it is
66 impossible to measure seismicity rate decreases, but increases extending ~25 km beyond the
67 ends of the South Napa rupture (marked '1' in Fig. 3c), as well as along several portions of
68 the Rodgers Creek and Green Valley faults (marked 2-5 in Fig. 4c) are evident. More
69 abundant seismicity rate increases to the north of the rupture could be a directivity effect of
70 its northward propagation (Brocher *et al.*, 2015; Dreger *et al.*, 2015). Comparison of Fig. 3a
71 with Fig. 3c shows that the shear stress is calculated to have increased on the nodal planes of
72 these remote aftershocks.

73

74 **COULOMB STRESS CHANGE ANALYSIS**

75

76 We first calculate the Coulomb stress change caused by the South Napa earthquake in
77 the surrounding crust and on the adjacent faults in an elastic half-space (Okada, 1992). We
78 use the variable slip model of Barnhart *et al.* (2015) inverted from 56 continuous GPS time
79 series, and from surface displacements from a coseismic interferogram by the JPL/ARIA
80 group. The rupture source is roughly 15 km long and 10 km wide, striking 341° and dipping
81 80°E. The rake, or slip direction, is fixed to 178° (right-lateral) for all sub-patches. Most of
82 the slip, up to 1.2 m, is concentrated on an 8-km-long central section, between 3-7 km deep.
83 We note that the model we used resembles the 2-plane source of Wei *et al.* (2015), which
84 also dips to the east and has the same overall strike and location. The source of Dreger *et al.*
85 (2015) dips 82°W, but is otherwise similar in seismic moment and extent, although it has
86 significant non-horizontal rake at the ends. All source inversions concur that rapid postseismic
87 slip increased the net moment to an equivalent M=6.1; the Barnhart *et al.* (2015) source that

88 we use includes 3 days of post-seismic slip in the GPS time series and a single interferogram.
89 Since the post seismic slip also contributes to the stress transfer, this inclusion is permissible.

90 We resolve the Coulomb stress changes on three types of ‘receivers’ (faults in the
91 surrounding crust that are subjected to stress changes caused by the South Napa source) to
92 assess whether fault slip is promoted or inhibited. Each approach has its own intrinsic
93 advantages and shortcomings; none takes precedence:

- 94 1) The first are vertical strike-slip receivers that, for a given fault friction coefficient, are
95 optimally oriented with respect to the combined regional stress and the Napa stress
96 changes (King *et al.*, 1994). Here we do not use mapped faults but instead attempt to
97 capture the role of small faults. We use this approach to determine if stress increases are
98 correlated with the distribution of aftershocks, since aftershocks need not occur on the
99 major mapped faults. The implicit assumption in optimally oriented Coulomb stress is
100 that small faults with a range of orientations exist everywhere in the crust; the faults with
101 the optimum geometry (on which the Coulomb stress increase is most positive), will be
102 most likely to host aftershocks (Fig. 1b). In Fig. S2, we explore the impact of the full
103 range of principal stress azimuths and fault friction on this result.
- 104 2) Next, we resolve the Coulomb stress changes on the mapped active faults within 50 km
105 (about three rupture dimensions from the source, beyond which the stress changes are
106 negligible, <0.05 bar), using the known or inferred fault rakes and dips compiled into the
107 UCERF3 fault model (Field *et al.*, 2014). The goal for this calculation is to estimate the
108 hazard changes on faults thought to be capable of $M \geq 7$ shocks (Fig. 4). In Fig. S3, the
109 full range of friction coefficients is explored.
- 110 3) Finally, we calculate the Coulomb stress change on the nodal planes of focal mechanisms
111 for events having occurred during 15 years before and two months after the South Napa
112 earthquake in and around the 2014 source fault (lon.: -122.7° to -122.0° , lat.: 37.9° to
113 38.6°). The nodal planes of shocks that struck before the Napa quake (Fig. 5b and Fig.
114 S4a-c) serve as proxies for small active faults, while the nodal planes of Napa aftershocks
115 (Fig. 5c and Fig. S4d) reveal which structures became active after the mainshock.

116

117 **Remote aftershocks concentrate in the stress-trigger lobes**

118

119 There are three elements needed for the calculation of the stress imparted to optimally
120 oriented strike-slip faults (receiver type 1 described above): The receiver fault dip and rake,

121 which we take to be vertical and right-lateral; the fault friction coefficient, which we assume
122 to be 0.4; and the regional stress tensor, which we simplify with an S_{Hmax} orientation and a
123 differential stress compatible with strike-slip faulting. We take S_{Hmax} from Townend and
124 Zoback (2004), who found a range of 22° - 46° (reckoned clockwise from North) for the Bay
125 area. We thus assume the σ_1 direction of the regional stress is 34° and its amplitude is 100
126 bar that is comparable to a typical earthquake stress drop (e.g., King *et al.*, 1994). We set σ_3
127 to be horizontal and perpendicular to σ_1 , with σ_2 vertical (Table 1). Close to the source
128 rupture, the stress imparted by the earthquake and the regional stress have roughly the same
129 magnitude, and so the optimal planes rotate. Far from the source, the optimal planes are
130 essentially fixed by the regional stress azimuth and the friction coefficient.

131 We find that about 90% of the off-fault aftershocks that struck during the first 53 days
132 occurred where the calculated Coulomb stress increased (Fig. 1b). Many aftershocks
133 occurred in the northern and southern stress increase lobes beyond the edges of the source
134 fault, and about 10 events occurred in the western and eastern side lobes. The greatest
135 number of shocks in one of the side lobes locates near the Green Valley fault, a finding we
136 first presented in Parsons *et al.* (2014).

137 138 **Several major active faults were stressed** 139

140 We represent the faults by contiguous rectangular patches (Fig. 4). For the Barnhart *et*
141 *al.* (2015) rupture source, and for the adjacent portions of the West Napa fault, the patches
142 are 4 km long x 2 km deep. For other faults within 20 km of the source, the patches are larger
143 (3-5-km long by 4.5-5-km deep), and for faults at greater distance, fault patches are <10 km
144 along strike and 10-15 km deep.

145 Our results indicate that portions of the Green Valley, West Napa, Contra Costa, and
146 Franklin faults were brought up to 0.5 bar closer to failure; the increase was >0.2 bar for a
147 length of 15 km along strike. In addition, a 6-km long echelon between the Rodgers Creek
148 and Hayward faults was also brought >0.5 bar closer to failure. Parsons *et al.* (2014) and
149 Barnhart *et al.* (2014) reported similar, independent findings. Parsons *et al.* examined two
150 values of fault friction at a single depth (0.2 and 0.4; which we also do in Fig. S3), and
151 Barnhart *et al.* examined two source fault dips (80° E and 76° W).

152

153 Exotic aftershock focal mechanisms reveal a heterogeneous stress field

154

155 The Coulomb stresses on the two nodal planes of a focal mechanism are different; to
156 avoid this ambiguity, we resolve the imparted shear stress only, equivalent to assuming
157 friction of zero. We find that the majority (~80%) of the aftershock focal mechanisms more
158 than 4 km of the source fault are calculated to have experienced shear stress increases.
159 (Figure 3a). The stress changes closer to the source are sensitive to details in the slip model
160 that may be artifacts of the slip inversion procedure (i.e. over-simplified fault geometry, rake,
161 and inversion regularization).

162 That a majority of mechanisms in Fig. 3a are positively stressed does not, in itself
163 mean that the mainshock stress promoted the aftershocks, if this same 80% percentage might
164 be found among the pre-mainshock, or background, shocks. To test causality, we perform the
165 same source-fault stress transfer calculation to the mechanisms during the preceding 15 years
166 (Fig. S4), and find that 40% are positive before the mainshock. The factor of 2 increase in
167 positively-stressed mechanisms means that the aftershocks were most likely promoted.

168 The Green Valley fault slips at 6 ± 1 mm/yr, about half of which occurs as creep
169 (Lienkaemper *et al.*, 2014). Paleoseismic investigation suggests a ~200-yr recurrence interval
170 for $M\sim 7$ shocks on the fault, and ~400 yr has elapsed since the last large earthquake
171 (Lienkaemper *et al.*, 2013). The fault also poses a substantial risk, since it bisects the city of
172 Concord, with 200,000 residents. Thus, perhaps the most important remote earthquake
173 cluster lies near the Green Valley fault (the eastern stress lobe in Fig. 1b, and the highlighted
174 rectangle in Fig. 3a).

175 The Green Valley seismicity cluster began 2-3 days after the mainshock, and contains
176 15 aftershocks with focal mechanisms. As can be seen in Fig. 1b, only a quarter of the events
177 occur in the stress-increase lobe for optimally-oriented faults in the assumed regional stress
178 field, while three-quarters strike in the stress decrease lobe. Yet, when the shear stress is
179 resolved on the nodal planes of the focal mechanisms along the Green Valley fault, the
180 proportion of positively stressed mechanisms rises from about 10% before the mainshock
181 (Fig. 5b) to 80% afterwards (Fig. 5c), consistent with the Coulomb hypothesis despite their
182 occurrence in the stress shadow for optimally oriented strike-slip faults. As before, the pre-
183 mainshock period serves as the control and the post-mainshock period as the test set; the
184 difference between the two sets is what matters. Hypocenters of the pre- and post-mainshock

185 clusters in the boxed area of Fig. 5 are remarkably close to each other; they lie within 2-3 km
186 (the mean depth of the pre- and post-mainshock clusters is 9.2 and 7.5 km, respectively).

187 The pre-mainshock mechanisms are consistent with right-lateral slip on the Green
188 Valley or smaller subsidiary faults in our inferred regional stress system (compare the
189 assumed stress field in Fig. 5a with that inverted in Fig. 5d), but the mechanisms activated
190 after the South Napa shock (Fig. 5c and Fig. 5e) are not. After the mainshock, the σ_1 inferred
191 from the focal mechanisms is oriented nearly perpendicular to the Green Valley fault (Fig.
192 5e), so these events most likely activate a different set of nearby faults. The stress tensor
193 inversions are simplified in the inset boxes in Fig. 5d-e.

194 At the site of the aftershock cluster, the Green Valley fault and optimally-oriented
195 strike-slip faults are inhibited from failure, but reverse faults parallel to the Green Valley are
196 promoted by ~ 1 bar (Fig. 5f). So, to explain the 65° clockwise change in the inferred σ_1
197 direction, there must be a nest of faults with many orientations, so that a different set of faults
198 could activate in response to the stress change. This can only occur if the tectonic stress is
199 much more heterogeneous than we have assumed, because only in a heterogeneous stress
200 field could both fault populations be active when the earthquake stress change is only 1 bar.
201 A similar Coulomb finding was reported by Toda *et al.* (2011) for the M=9.0 Tohoku-Oki
202 megathrust earthquake, whose shallow aftershocks were largely normal events. Stress
203 heterogeneity was proposed as a widespread phenomenon by Smith and Dietrich (2010), and
204 further explored by Smith and Heaton (2011).

205 The focal mechanism analysis reveals why, while widely practiced, resolving the
206 stress on assumed optimal orientations (Fig. 1b), or on major active faults (Fig. 4), can be
207 misleading: Even though the burst of aftershocks lies within 2 km of the Green Valley fault,
208 they are unlikely to have anything to do with the Green Valley fault, and their orientation is
209 optimal only for a unique and quite local tectonic stress condition.

210

211 **HEIGHTENED PROBABILITY OF GREEN VALLEY FAULT RUPTURE**

212

213 We next seek to estimate how the South Napa earthquake altered the likelihood of
214 failure on the Green Valley fault. As evident in Fig. 4, a 15-km-long section of the fault was
215 brought <1.0 bar closer to failure, but the adjacent 20-km-long section to the south was
216 inhibited from failure by up to 2.0 bar. The net effect over the 35-km-long section is negative
217 (-0.5 bar). So, what is important, the local increase or the net decrease?

218 The stress transfer from the South Napa earthquake to the Green Valley fault,
219 resembles the transfer from the 1992 M=7.3 Landers shock to the Lavic Lake fault—which
220 subsequently ruptured in the 1999 M=7.1 Hector Mine shock (Fig. 1c). Further, the Landers
221 earthquake also produced remote aftershocks near, but not on, the Lavic Lake fault with a
222 non-parallel focal mechanisms (Hauksson *et al.*, 2002), and so these cases are remarkably
223 similar. Another example is the 1997 M=6.5 and 6.3 Kagoshima, Japan, earthquakes (Toda
224 and Stein, 2003); in both the California and Japanese sequences, the second earthquake
225 nucleated on or near a promoted section of the fault, and then propagated into or through
226 inhibited sections. These examples suggest that under some circumstances, what counts is the
227 peak stress increase, even if it is isolated.

228 So, use the calculated 0.6-bar Coulomb stress imparted by the Napa mainshock, and
229 the seismicity rate equation of Dieterich (1994) to calculate the expected response of
230 seismicity to the stress jump. We then calculate the time-dependent probability of a surface-
231 cutting earthquake on the Green Valley fault unperturbed by the South Napa event, using the
232 paleoseismic occurrence information from Lienkaemper *et al.* (2013): a 250-yr interevent
233 time with a 0.6 coefficient of variation, and 400 yr since the last event. This yields a 30-yr
234 probability of 18.5%.

235 This rate/state Coulomb calculation is sensitive to the assumed aftershock duration
236 and a fault constitutive parameter on the Green Valley fault, creating considerable
237 uncertainty. Aftershock duration is the time until the seismicity rate returns to the pre-
238 mainshock rate; it can be measured on the source fault or on a nearby receiver. In general, we
239 have found that aftershock durations grow with distance from the San Andreas, probably
240 because the stressing rate declines with distance (Table 3). On the South Napa fault, we
241 project the aftershock duration to be 7-10 yr (Fig. S5). We have generally inferred the fault
242 constitutive parameter times the normal stress, $A\sigma$, to be about 0.5 bar (Toda and Stein,
243 2002; Toda *et al.*, 2005). The fault stressing rate is proportional to slip rate for isolated faults
244 of the same length; rates of 0.05-0.5 bar/yr bracket the likely range of this fault. The resulting
245 range of probabilities is shown in Fig. 6, of which we consider the blue curve (a 5-yr
246 aftershock duration and 0.1 bar/yr stressing rate) to be the best or median estimate. If so, the
247 South Napa shock will have elevated the $M \geq 7$ probability modestly for up to several decades.

248

249 **CONCLUSIONS**

250

251 Despite a very low aftershock productivity, the South Napa $M=6$ earthquake has a
252 high proportion of remote aftershocks that occur up to 25 km from the rupture. Coulomb
253 stress calculations indicate that these aftershocks were generally promoted by the stress
254 imparted by the mainshock, even when the faults on which these quakes struck differed
255 substantially in orientation from the major surface faults, or those expected to be optimally
256 oriented in a simple uniform tectonic stress field. Subsequent large earthquakes on the West
257 Napa fault to the north, the Franklin and Contra Costa faults to the south, and the Green
258 Valley fault to the east, would appear possible because 15-km or longer sections of all of
259 these faults received a calculated stress increase of more than 0.5 bar. Because paleoseismic
260 evidence indicates that surface-cutting ($M>6.5$) ruptures on the Green Valley fault have
261 occurred every 250 ± 150 yr, and 400 yr has elapsed since the last event, this urban fault bears
262 special scrutiny.

263 Furnishing a time-dependent probabilistic rupture forecast on the Green Valley fault
264 is uncertain because the northern portion received a calculated stress increase while the
265 central portion a decrease. But the resemblance between the stress imparted to the Green
266 Valley fault by the South Napa mainshock, and the stress imparted to the Lavic Lake fault by
267 the Landers earthquake, encourages us to base our calculation on the 15-km-long patch of the
268 Green Valley fault brought 0.6 bar closer to failure. This results in the 30-yr earthquake
269 probability rising from 18.5% to as high as 22-25%, which is forecast to decay back to 19%
270 over the next 5-20 years. Further monitoring of seismicity and strain on the Green Valley
271 fault would seem prudent, given this modest and uncertain hazard increase.

272

273 **ACKNOWLEDGEMENTS**

274

275 We thank Tom Parsons, Andrea Llenos, Jim Lienkaemper, Tim Dawson, and Volkan
276 Sevilgen for insights and discussion. We are also grateful to William Barnhart and Deborah
277 Smith for their thoughtful and careful reviews.

405 **Figure Captions**

406

407 **Fig. 1.** (a) Moderate earthquakes during the past 36 yr in the San Francisco Bay area show
408 an active corridor extending from Loma Prieta to the East Bay faults, of which the 2014
409 South Napa earthquake is only the most recent part. The Bay area is complete for $M \geq 4.1$
410 since 1942 (Felzer, 2013). (b) Maximum Coulomb stress change, using the Barnhart *et al.*
411 (2015) source, on optimally oriented strike-slip faults at depths from 5 to 15 km. The
412 regional stress field is assumed as shown in Table 1, and the coefficient of fault friction is
413 set to be 0.4. Black lines denote the surface traces of the late Quaternary faults, younger
414 than 130,000 years compiled by the USGS (2006). All recorded aftershocks during the
415 first 53 days are plotted (24 August-16 October 2014). (c) A calculation from King *et al.*
416 (1994) for the 1992 $M=7.3$ Landers earthquake bears a resemblance to the South Napa
417 source-Green Valley fault configuration.

418

419 **Fig. 2.** Aftershock productivity and decay for three $6.0 \leq M \leq 6.1$ California mainshocks. The
420 areas from which the earthquakes were extracted is given in Table 2; each uses 60 days.
421 It is evident that while they all have about the same temporal decay slope ($p \sim 1$), the
422 South Napa quake has a much lower productivity than the others.

423

424 **Fig. 3.** (a) Shear stress change resolved on aftershocks of the South Napa mainshock, with
425 the area of Fig. 5 identified. (b) Seismicity in the first two months after the mainshock. (c)
426 The seismicity rate change associated with the mainshock, formed by the ratio of the rate
427 during the first two months after the mainshock to the preceding 5 yr. Areas for which the
428 rate change is undefined (principally because of the absence of earthquakes during either
429 period) are grey. In addition, the post-mainshock period is too short to identify seismicity
430 rate decreases. Salient off-fault rate increases are numbered.

431

432 **Fig. 4.** Coulomb stress change resolved on the Bay Area faults of the Uniform California
433 Earthquake Rupture Forecast version 3 (UCERF3, Field *et al.*, 2013). The Green Valley,
434 West Napa, Contra-Costa, and Franklin faults are split into 3-5-km long by 4.5-5-km wide
435 sub-patches and stress is calculated on the center of each sub-patch. For these faults
436 there is an expanded view at right Colors saturate at ± 0.5 bar.

437

438 **Fig. 5.** Mainshock-induced stress and focal mechanism changes near the Green Valley
439 fault. (a) Our assumed tectonic stress, from Townend and Zoback (2004), drives the right-

440 lateral Green Valley fault. (b) Pre-mainshock focal mechanisms are consistent with the
441 stress field in (a). After the mainshock, a larger percentage of mechanisms were
442 promoted; here (b) is the control set and (c) is the test set. (d) The principal stress axes
443 for the pre-mainshock period, 2009-2013, derived from 2,000 bootstrap resamplings
444 using the MSATSI software (Martinez-Garzon *et al.*, 2014), match the assumed principal
445 stress in (a); R is relative stress magnitude. (Only 12 mechanisms are available during
446 the post South Napa period. Since the minimum number the software accepts is 20
447 seismic events, we simply doubled the original data to 24 events before resampling.) The
448 stereo nets projected onto the lower hemisphere are simplified in the inset boxes. (e) For
449 the post-mainshock mechanisms, the inferred principal stress axes are oriented $\sim 65^\circ$
450 clockwise. (f) The mechanisms in (c) are promoted by the stress imparted by the
451 mainshock. (Additional pre-mainshock mechanisms are shown in Fig. S4.)

452

453 **Fig. 6.** Calculated 30-yr probabilities of a surface-rupturing earthquake on southern Green
454 Valley fault as a function of time. The probability jump followed by a decaying probability
455 is caused by the sudden stress change associated with the $M=6.0$ South Napa
456 earthquake. The inter-event time, elapsed time, and coefficient of variation are based on
457 geologic data of Lienkaemper *et al.* (2013). Three different aftershock durations, t_a , are
458 assigned with the range of the estimates in Table 3; τ is the fault stressing rate.

Table 1. Regional stress tensor used for Coulomb stress change on optimally oriented strike-slip faults in Fig. 1b.

	Azimuth (°)	Plunge (°)	Magnitude (bar)
σ_1	34	0	100
σ_2	34	90	30
σ_3	124	0	0

Table 2. Comparison of 60-day aftershock productivity between the three M~6 strike-slip, California earthquakes, in Fig. 2.

Mainshock	M	Number of $M \geq 1.8$	Number of $M \geq 4.0$	Maximum aftershock magnitude	Search area (lon./lat., polygon)
2014 South Napa	6.0	64	0	3.9	-122.700°/38.600°, -122.000°/38.600°, -122.000°/37.900°, -122.700°/37.900°
2004 Parkfield	6.0	548	9	5.0	-120.729°/36.066°, -120.617°/36.140°, -120.189°/35.758°, -120.306°/ 35.673°, -120.730°/36.066°
1992 Joshua Tree	6.1	3108	19	5.0	-116.500°/34.250°, -116.000°/34.250°, -116.000°/33.800°, -116.500°/33.800°

Table 3. Estimated aftershock durations for California earthquakes

Mainshock and Evaluated Fault	Aftershock duration (yr)	Distance from San Andreas fault (km)	Source of Estimate
Parkfield, creep & transition sections	0.5-3.0	0	Toda and Stein (2002)
Parkfield, 1966 locked section	3-10	0	Toda and Stein (2002)
2004 M = 6.0 Parkfield, section	2	0	This study
1992 M = 6.5 Big Bear fault	7	10-20	Toda & Stein (2005)
1987 M = 6.6 Superstition Hills fault	15	20-30	Toda & Stein (2005)
1989 M=6.9 Loma Prieta on San Gregorio f.	5-15	30-40	Stein (1999)
2014 M = 6.0 on West Napa fault	7-11	40-50	This study
1989 M=6.9 Loma Prieta on Hayward fault	7-11	40-50	Stein (1999)
1992 M = 7.3 Landers on Landers fault	25-50	50-70	Toda and Stein (2005)
1999 M = 7.1 Hector Mine, Lavić Lake fault	66	70-80	Toda and Stein (2005)
1995 M = 5.8 Ridgecrest on ECSZ faults	17-30	140	Toda and Stein (2005)

Electronic Supplement to
2014 M=6.0 South Napa earthquake triggered widespread aftershocks
and stressed several major faults
and exotic fault clusters by Shinji Toda and Ross S. Stein

These five figures explain further details of our seismicity and stress analyses.

Figure S1. Cumulative (a) and interval (b) background seismicity rate and magnitude of completeness, M_c . The slope of the cumulative number of earthquakes has been stable from 2004, with a slightly lower rate after \sim 2007. The magnitude of completeness (M_c) as a function of time following Woessner and Wiemer (2005) as implemented in the ZMAP software (Wiemer, 2001) is shown with ± 1 sigma bounds.

Figure S2. The 95% confidence interval on the principal stress orientation from Townend and Zoback (2004), and on the friction coefficient, are explored for the optimally-oriented Coulomb stress change on strike-slip faults (a, b, d, e), and compared to an assumed fixed fault orientation (c, f).

Figure S3. The influence of fault friction on the Coulomb stress imparted to the major mapped active faults. Note that regardless of friction, portions of the Green Valley fault are brought closer to failure.

Figure S4. Shear stress changes resolved on the nodal planes of small earthquakes that occurred prior to (a-c) and after (d) the 2014 South Napa earthquake, as proxies for the sites of small active faults. Fault plane solutions are from the Northern California Earthquake Data Center (NCEDC, <http://ncedc.org/ncedc/catalog-search.html>). Color of compressional region on each beach ball indicates amount of stress change. We split the pre-South Napa period into three

sub-periods to avoid overlapping beach balls in the maps. Blue lines are mapped late Quaternary faults.

Figure S5. Observed aftershock rates (dots) as a function of time for the South Napa earthquake, fitted to an Omori-Utsu function (solid line), $N(t)=k/(t+c)^p$. Two areas, I and II in inset map, are applied to the analyses. Together with observed background rates of $M \geq 1.5$ as M_c from Fig. S1, we estimate aftershock durations, t_a , for the wider area I and the narrower area II several months and several years respectively.
